Introduction

Whenever additional information needs to be inserted into an existing document without altering the original text, we can make use of annotations. They usually take the form of footnotes, which require only a minimal reference in the main text, and are used for a variety of reasons - for example, to provide additional information that would hinder the text's flow if inserted directly, or as a result of a commenting tool that is used for communication between an author and their editor. If a more obvious connection between the text and the referenced content is required, for example when lengthy comments are added, or if a change-tracking tool is used, the reference is often placed to the side of the document and visibly connected to the part of the text it is referring to. This style of annotation is easily implemented on virtual documents, since they can be hidden on demand, however if the annotations need to be included in a printed version, there are several issues that arise regarding readability of the final product and ambiguity of text-annotation assignments.

In this thesis, we will look at ways to use Boundary Labeling for this problem, which means that all annotations will be placed somewhere outside of the text they are referencing and will be visually connected to the feature they are referencing. (See also [3])

The guidelines on how to create suitable labelings are as follows: the connections should be as direct as possible, no important information should be obscured, and it should be easily discernable which Label belongs where. These three criteria easily come into conflict with one another, as the text usually is very dense and leaves little space for lines in between, yet one shouldn't allow them to pass through the text, as this makes the text harder to read.

1.1 Terminology and Fundamentals

Boundary Labeling (or equivalent concepts) can be applied to a space with different geometry or more dimensions, but this thesis will only concern itself with two-dimensional,

Figure 1.1: Illustrated guide to the labeling terminology

Euclidean space. To easily reference important concepts, some additional terminology will be introduced as well. (See Fig. 1.1 for a visual explanation)

A *graph* $G = \langle V, E \rangle$ is a tuple of *vertices* $V = \{v_1, v_2, \dots, v_n\}$ and *edges* $E = \{e_1, e_2, \dots, e_m\}$. A vertex v is a featureless object. Each edge e is a relation between two vertices $E \subseteq V \times V$. We call two vertices $u, v \in V$ *adjacent*, if the edge $e = (u, v) \in E$. A *path* $P = v_1, \dots, v_h$ is an ordered sequence of vertices, where each vertex must have an edge connecting it to the subesquent one. *Depth-first search* is a searching algorithm on a graph G that starts at a given vertex $v \in V$ and explores the graph by traversing its edges as far as possible before backtracking, and continues to do so until a pre-defined goal is met.

A *Polyline* is a curve defined by a sequence of points $O = p_1, p_2, \dots, p_n$, connecting each point to its successor with straight lines. Each point $p \in O$ cannot be equal to any other point in O . We will call a polyline *monotone*, if it satisfies certain conditions. For *monotonically increasing* polylines, each two vertices must satisfy the following: $\forall p_i, p_j \in O : i < j \iff (X(p_i) \leq X(p_j) \wedge Y(p_i) \leq Y(p_j) \wedge p_i \neq p_j)$, where $X(\cdot)$ returns a point's X-coordinate, and $Y(\cdot)$ returns its Y-coordinate. For *monotonically decreasing* polylines, the inverse must be true - each point must have at least one coordinate with a value smaller than its predecessor. *Labels* hold additional information and are represented as boxes containing this information. They always have a *port*, a special point on the label's border which will be defined later. Labels are usually placed in the *label area* which is a rectangular area designated to hold labels. It is located next to of the bigger, rectangular *text area*, which contains the document's text and all *sites*, the points or objects that a label's information refers to. If multiple label areas exist on different sides of the text area, we speak of *multi-sided labeling*, otherwise we speak of *one-sided labeling*. We will be using one-sided labeling in our implementation. Some space was left in between the text and label area, to make connecting sites to their labels easier, which we will call the *routing area*. The site and the label are connected via a *leader*, a polyline that can be further classified by looking at the orientation of its segments: *O-Segments*

run orthogonally to the border of the label area. *P-Segments* run parallel to the border of the label area, and as such must be combined with other segments for the leader to reach its destination. *S-Segments* are not required to have any particular orientation, and simply connect their start and ending points in a straight line. The leader's name is created by combining the name of the segments - for example, the blue leader from Fig 1.1 would be classified as an OPOPO-Leader. The location where a leader connects to the label is called the *port*. It can be restricted to pre-defined positions.

1.2 Related Work

Boundary labeling was first introduced by Bekos et al. in 2004 (see [3]), where both one-sided and multi-sided labelings with different leader types are looked into. They also showed that the optimal placement of arbitrarily-sized labels on two sides of the text area can be NP-hard by drawing comparisons to the Partition-Problem. However, a pseudo-polynomial solution exists for this problem, which was adapted to this variation of the problem.

Since then, several papers have been written about boundary labeling. One of these is [2], which looks into the readability of different leader styles. Interestingly, some leader styles perform quite well, despite the study's participants preferring others over them, with OPO-Leaders being both least preferred and the hardest to follow.

Another article using boundary labeling is [4] by Götzelmann et al., which creates boundary labeling-style annotations along other methods to label different parts of three-dimensional figures, resulting in pictures similar to what could be found in a textbook. As this algorithm works in real-time, it is suitable for labeling interactive models and allows for user interaction.

Boundary labeling in text documents however, is rarely discussed, and only few papers exist about this topic. The programs that employ this style of annotation often also use rather simple algorithms, to mediocre results or make extensive use of the interactivity of a digital medium, showing annotations only on demand. However, the few papers that approach this topic add interesting information to the discussion.

The paper about the Luatodonotes-Package[5] uses several styles of drawing leaders, and came to the conclusion that leaders without bends are easier to follow, which fits with [2]'s observations, which ranks OPO- and PO-Leaders lower than other variants. However, most solutions proposed in [5] do not consider whether a path overlaps with text or not, which results in a decrease in readability. While we do not use the routing and leader styles introduced in this paper, the results can be used in comparisons regarding readability of the main text and ease of use of the different leader styles.

The thesis by Loose[7] on the other hand is based around only using the free space between lines and words, which produces longer leaders, and forces curves, but doesn't obscure any part of the text. The two different approaches in this paper were a clustering-based algorithm, which was previously described in [8], and a flow network-based approach. Several concepts of this paper, such as the graph-based strategy and the usage

of a routing area will be adopted in our thesis and it is by far the biggest influence on our approach to the problem.

Lin et al.[6] use only OPO-Leaders that have their P-Segment located outside of the text area in their paper, but allow the leaders to use the text area's border on the opposite side of the label area to route upwards or down. This allows for more labels to be placed as close as possible to their leader's source, at the cost of increasing select leaders' length and placing some labels out of order. While this is an interesting way to avoid longer leaders in general, it is hard to combine with the graph-based routing that happens inside the text area, so we won't make use of it.

The Algorithm

2.1 Problem Specification

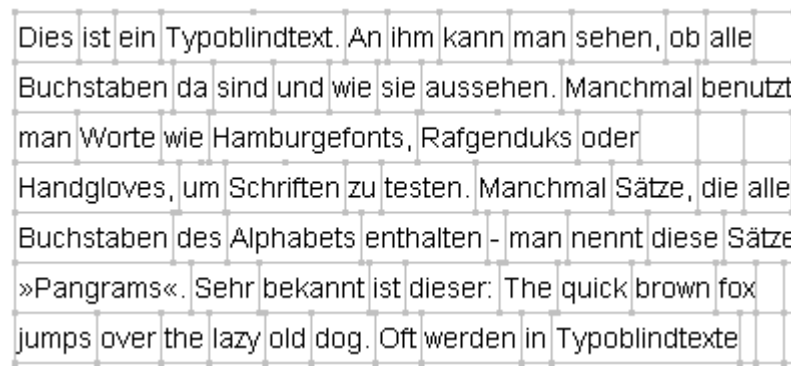

We limited the leaders to use exclusively O- and P-Segments, and banned them from passing through words. We also place labels as far up as possible to maximize the space remaining for remaining placements. Additionally, a leader isn't allowed to be any longer as is necessary to connect a given Site with its label's port.

These restrictions are implemented as follows: We divided the text T into separate lines $L = \{W, H\}$ which are in turn made up of words W and whitespace H . The remaining space between lines is called $S = \{s_1, \dots, s_{n+1}\}$, with n being the number of lines in L . For each $l_i \in L$, s_i is the space directly above that line. All $s \in S$ are the same height and width, even s_1 and s_{n+1} , which only have lines on one of their sides. For each word $w \in W$, we define $R(w)$ as its bounding rectangle, which marks the space leaders aren't allowed to cross. For a graphical representation see Fig. 2.1a.

Since we only allowed the Usage of O- and P-Segments in leaders, the only way for a leader to cross through a line of text is with a P-Segment through whitespace, whereas O-Segments are only usable between lines. Therefore, we can create a routing graph $G = \langle V, E \rangle$ whose Edges E reflect the legal paths a leader can take within T . For each line $l_i \in L$ and each whitespace character $h \in l_i$, one vertex is placed in s_i and s_{i+1} each, located above or below the whitespace character, and with a maximum distance from each of its neighbouring lines. The start and end of each line are also assigned a pair of vertices each. Sites will be represented by the insertion of additional vertices in S_i on a similar height as those next to whitespace of the same line and located directly above the center point of its words w_j bounding rectangle $R(w_j)$. The edges between the vertices are all perfectly horizontal or vertical, and do neither intersect with any bounding rectangle, nor any vertices other than their starting and ending vertex. The resulting graph looks similar to Fig. 2.1b. We will call the vertices closest to the text area's border to the routing area *Border Vertices* $B \subset V$. They serve as a goal for the depth-first search, and are located at the end of each line in our implementation.

(a)

(b)

Figure 2.1: Visualization of the space reserved for the text, and the resulting graph.

Each edge has a capacity of 1, meaning that no more than one leader is allowed to pass through it. Leaders also aren't allowed to cross one another, as it is hard to discern between intersections and two leaders curving away from each other. Furthermore, they are monotonically increasing, and go as far up as possible, limited only by the previous label's placement.

The Routing Area will be used to connect each site's path with its source, using OPO-Leaders. Combined with the path $P = \{s, v_1, v_2, \dots, v_b\}; P \subset V$ leading from the source $s \in S$ to the graph's border ($v_b \in B$) it creates an unbroken connection between a source and its port, which shall be called a *Source-Port-Path*, or *SP-Path*.

2.2 Description

The routing algorithm works through the annotations $a \in A$ in the order they appear in the text, placing each as far up as possible, skipping any annotation that cannot be placed above its leader's source or is impossible to route. It will use fixed ports located in the top left corner of each label.

The routing algorithm itself uses a depth-first-search algorithm, with the Graph G and the set of sites $V_{ann} \subset V$ as input. The Algorithm terminates either when reaching the right text border or if all possible paths failed to reach the text border, and the resulting SP-path will be monotonically increasing. This path is split into two parts: The path within the graph ($P \subset V$), leading from the source to the text area's border, and the OPO-Leader that connects the text area's border with the Label's port. The former is implemented as a list of vertices $V_{Path} \subset V$ the leader travels through, whereas the latter is determined by the rightmost vertex of V_{Path} , the Port, and the location of the P-Segment. **If the routing for any given site failed, the algorithm returns \perp .** (For an illustration in Pseudocode see Alg. 1.)

Each SP-path's P-Segment in the Routing Area is only placed after all SP-Paths have been generated, and will be placed with equal spacing between the borders of the Routing Area and each P-segment, to ensure readability of the resulting leaders.

<pre> Data: A single annotation's source and its Graph Result: A List of vertices describing the leader's path 1 initialization 2 while currentVertex <i>not at right text border</i> do 3 if (Graph.getTopNeighbourOf (currentVertex) \neq null) \wedge \negbacktracking 4 then 5 Path.addVertex(currentVertex) 6 currentVertex \leftarrow Graph.getTopNeighbourOf (currentVertex) 7 else if Graph.getRightNeighbourOf (currentVertex) \neq null then 8 Path.addVertex(currentVertex) 9 currentVertex \leftarrow Graph.getTopNeighbourOf (currentVertex) 10 backtracking \leftarrow False 11 else 12 backtracking \leftarrow True 13 repeat 14 oldVertex \leftarrow currentVertex 15 currentVertex \leftarrow Path.getLastEntry() 16 Path.RemoveVertex(currentVertex) 17 until currentVertex's <i>Position is below oldVertex or Path is Empty</i> 18 19 if currentVertex <i>not below oldVertex</i> then //No path found 20 break 21 end 22 end 23 end </pre>
--

Algorithm 1: The Depth-First-Search algorithm used in the program.

2.3 Analysis and Proof

In this section we will analyze the following:

- Computation time of graph-creation
- Computation time of the routing algorithm for single leaders
- Overall computation time of the routing algorithm

Furthermore, we will prove that:

- The algorithm always returns a shortest path
- The algorithm generates only crossing-free routings
- The algorithm places as many annotations as possible
- The algorithm keeps the annotations in reading order

CHAPTER 3

Implementation

The program was written in Java 1.8.0u40, using JGraphT1.0.1[1] as graph library. Since we only want to create leaders that don't intersect with the text, the graph was created alongside the placement of the words on the canvas.

3.1 Challenges

Evaluation and Testing

- 4.1 Data generation
- 4.2 Testing methods
